Abstract: For replacing the un-ecofriendly gold recovery methods, photoreduction catalyzed by TiO₂ is proposed as an environmentally benign alternative method for gold recovery. In this study, the photocatalytic reduction was carried out by batch technique, in which the influences of reaction time, TiO₂ photocatalyst dose, and initial Au(III) concentration were evaluated to get the optimal condition. In addition, the influence of Ag(I), Cu(II), and Fe(III) that are usually found along with gold in the gold mineral is also studied. The research results indicate that the effective Au(III) photoreduction catalyzed by TiO₂ has produced brown solid powder of gold element. It is also found that the effectiveness of Au(III) photoreduction is controlled by reaction time, Au(III) initial concentration, and photocatalyst dose. Furthermore, the presence of Ag(I) and Cu(II) ions leads to the gold photodeposition decreased, meanwhile the presence of Fe(III) ion can enhance the photoreduction. It is clear that photocatalytic method is a promising method for gold recovery, with respect to the easiness, cheapness, and eco- friendliness.

Keywords: Photoreduction, TiO₂, Gold, Recovery, Ag, Cu, Fe

1. Introduction

Gold (Au) is well known as a high valuable metal, forcing a lot of peoples from ordinary communities to big companies to explore and recover it. In Indonesia, gold core minerals are widely found and have been explored intensively. The well known gold extraction methods are amalgamation and cyanidation [1]. Amalgamation using mercury is more frequently used because it is practically simple and effective. However, this method always releases mercury containing wastewater in high level that contaminate environment including air and rivers. Since mercury is toxic pollutant, pollution by mercury could destroy the environment and consuming food and drinks contaminated by mercury can lead to several serious health problems [2-3]. The other gold extraction method called cyanidation uses cyanide salt. At the end of the process, the waste water containing cyanide complex compounds is always resulted. The cyanide complex compound in the acid solution will form volatile high toxic cyanide acid, which is also toxic for people and the environment [2-3]. It is clear that both methods for gold

extraction are hazard for people and environment. Therefore, an afford to develop alternative environmentally benign methods is strongly required.

In the hydrochloride solution, gold is usually formed as ion AuCl₄⁻, that is easy to be reduced into Au⁰ or gold metal, indicated by its high reduction potential, i.e. 1.04 V [4]. Accordingly, various types of reduction methods have been explored for gold recovery, including electrolysis [5], adsorptive-reduction [6-9], and bioreduction and biorecovery [10-13].

The other potential reduction method is photocatalytic reduction, which is a simultaneous reduction using UV light and sensitized with semiconductor photocatalyst such as TiO₂ [14]. Such method has been intensively studied to detoxify Cr(VI) [15-17], Hg(II) [18-19], Cu(II) [20-21] as well as to recover Ag(I) [22]. Moreover, the method has also been assessed for gold photodeposition [23], but very limited publication is searched.

In this paper, gold photodeposition from Au(III) solution by photocatalytic reduction in the presence of TiO₂ is reported. The influence of some operating factors such as

photoreduction time, photocatalyst dose, and Au(III) initial concentrations, is systematically evaluated. In addition, the effect of the presence of Ag(I), Cu(II), and Fe(III) that are usually found along with gold in the mineral is also examined.

2. Experimental Method

2.1. Chemicals

The chemicals used were TiO₂, Au(NO₃)₃, AgNO₃, Cu(NO₃)₂, Fe(NO₃)₃, HCl, and NaOH pellet in analytical grade purchased from E.Merck and used without any purification.

2.2. Procedure of Photoreduction

Photocatalytic reduction of Au(III) solution was carried out in a closed equipment installed with a 40 watt UV lamp having wavelength in the range of 290-390 nm, as illustrated by figure 1. The reaction was performed by irradiating 50 ml nitrate solution of 50 mg/L of Au(III) ions mixed with 25 mg TiO₂ powder, with UV light accompanied by magnetic stirring for 24h. The mixture was filtered and the solution obtained then was analyzed by Perkin-Elmer AAS to determine the concentration of the unreduced Au(III) ions. By subtracting the initial Au(III) concentrations with the unreduced one, the amount of Au(III) photoreduced could be calculated. The gold resulted from the photoreduction was also confirmed by scanning electron microscope (SEM).

Fig. 1. A set of equipment for photoreduction.

In this study, the influences of photoreduction time, TiO₂ dose, and initial concentration of Au(III) in the solution, and the presence of Ag(I), Cu(II), and Fe(III) were also systematically studied, by varying the variables, as presented in Table 1.

Table 1. The variations of the variables studied.

Mass of TiO ₂ (mg)	5, 15, 25, 50
Reaction time (h)	1, 5, 10, 24, 50, 100
Concentration of Au(III) (mg/L)	5, 10, 25, 50, 100
Concentration of Fe(III) (mg/L)	50
Concentration of Cu(II) (mg/L)	50
Concentration of Ag(I) (mg/L)	50

3. Results and Discussion

3.1. The Influence of TiO₂ Photocatalyst

The effectiveness of Au(III) taken from the solution by using three different condition processes is shown in Fig.2. It is seen in the figure that by irradiating the solution, Au(III) ions in the solution can be taken out although with low effectiveness. In this process, Au(III) ion is reduced into Au(0) or gold elemental by electron released from water photolysis as written in eq.1.

Fig. 2. The uptake of Au(III) from the solution by different processes.

The water photolysis takes place very slowly [24] giving very few electrons. This explains the low effectiveness of the photoreduction. Furthermore, the figure also exhibits the significant improvement of Au(III) photoreduction when the process was added with TiO₂. Due to its structure, TiO₂ can release electron effectively during the light exposure [14, 24-25], as written as eq.2. This condition may provide more number of electrons that promote the high effectiveness of the photoreduction. The photocatalytic reduction of Au(III) by TiO₂ is written as eq.3.

Figure 2 also demonstrates that the process with TiO₂ but without light (dark condition) can take the Au(III) out from its solution in lower amount compared to the process with light and TiO₂. The Au(III) taken out from the solution may occur through adsorption mechanism, because in the dark condition no electrons for reduction, are available. The adsorption takes place on the surface of TiO₂ through entrapment on the dangling bonds and/or via electrostatic interaction [26]. It is clear that in the photocatalytic gold reduction is initiated and/or accompanied by adsorption, that is continued by photocatalysis reduction of the Au(III) adsorbed [25, 27-28].

3.2. The Influence of the Photocatalyst Dose

Regarding the efficiency of the photocatalytic process, optimization of the photocatalyst dose is important to study.

The influence of TiO₂ photocatalyst dose on the effectiveness of Au(III) photoreduction is illustrated by figure 3.

Fig. 3. The influence photocatalyst dose.

The figure indicates that Au(III) photoreduction improves with the increase of TiO₂ dose, but further enlargement of TiO₂ dose causes a decrease in the photoreduction. The increase of TiO₂ mass provides more number of electrons resulting in higher photoreduction. The dependency of the photoreduction on the photocatalyst mass is extended up to 25 mg/50 mL dose. The excess of TiO₂ mass can increase the turbidity that creates a light screening effect, that reduce the surface of TiO₂ being exposed to the light irradiation. Consequently, the less electrons are released [24-25], leading to the less effective photoreduction.

3.3. The Influence of Photoreduction Time

Other important factor controlling the effectiveness of the photoreduction is reaction time. The results of Au(III) photoreduction carried out in various periods of time is presented in figure 4. The figure displays the photoreduction is proportional directly to the time extension up to 24 h. But the photoreduction is not dependent on the time at over than 24 h. The longer reaction time makes the interaction between TiO₂ and light is more effective, providing much more electrons to the system. In addition, more effective interaction between the electrons and Au(III) ions in the solution also proceeds. Both conditions strongly promote the higher effectiveness of the photoreduction [27-28].

Fig. 4. The influence of the photoreduction time.

When the reaction time was further extended, high amount of gold has already been photodeposited and covered the surface of TiO₂ photocatalyst, causing less active photocatalysis. This explains why the Au(III) photoreduction remains constant.

3.4. The Influence of Initial Au(III) Concentration

In order to find out the information of Au(III) concentration that can be photodeposited maximally, photocatalytic reduction of Au(III) in the various concentrations was also carried out and the results are displayed as figure 5.

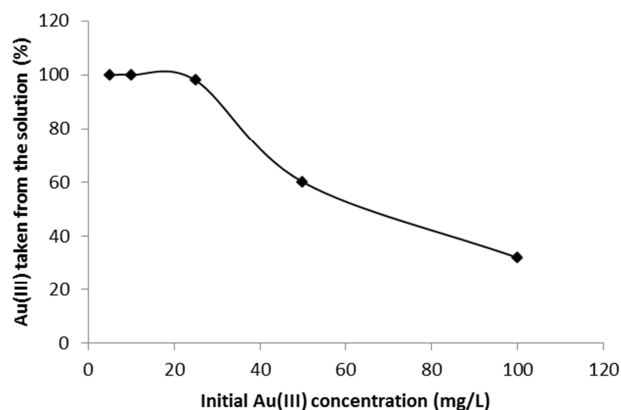

Fig. 5. The influence of Au(III) initial concentration.

It is demonstrated by the figure that for low concentration (5-20 mg/L), Au(III) ions can be photoreduced completely and the photoreduction decreases gradually with the increasing Au(III) initial concentration. This data relates with the capacity of the photocatalyst, wherein the low number of Au(III) ion with the adequate number of electrons provided by TiO₂, promotes effective photoreduction until reach maximum level. Moreover, although, the Au(III) concentration in the solution is further increased, but with the constant mass of TiO₂, providing same number of electrons in the solution, the photoreduction does not arise or keeps constant [27-28].

3.5. The Influence of Ag(I), Cu(II), and Fe(III) Ions in Gold Photodeposition

In the gold core, gold element is always accompanied with other metals including silver, copper, and iron. For gold photodeposition, the gold core has to be digested in strong acid that make the metal presence are dissolved to form Au³⁺, Ag⁺, Cu²⁺, and Fe³⁺ ions. The metal ions are known as reducible ions [4], that may influence on the gold photoreduction. Accordingly, the influence of the three metal ions on the gold photodeposition is also studied. In the solution studied, the concentration of all ions are arranged to be same, that are 50 mg/L and the results are illustrated by figure 6.

The figure illustrates that the presence of Ag(I) and Cu(II) lead to a decrease in Au(III) photoreduction, and the effect of Cu(II) is stronger than Ag(I). Meanwhile the photoreduction is enhanced when Fe(III) is present. Both Ag(I) [22] and Cu(II)

[20-21] can be photoreduced, assigned by respective standard reduction potentials as much as 0.799 V and 0.34 V, to form Ag(0) and Cu(0) respectively, that creates competition to Au(III) photoreduction. Based on their standard reduction potential, it is known that Ag (I) is easier to be reduced than Cu(II) is, that should give larger effect, but the opposite data is observed. In addition the standard reduction potential of Cu(II) is much lower than that of Au(III), implying that reduction of Cu(II) is more difficult that should not give effect on Au(III) photoreduction. It is clear that the stronger effect shown by Cu(II) on decreasing Au(III) photoreduction is not caused by competition in the photoreduction, but is prominently caused by adsorption of Cu²⁺ on the surface of TiO₂, as also reported by Wahyuni, et al, [17]. As presented previously, the photocatalytic reduction process is always initiated and/or accompanied with adsorption of Au(III) ions on the surface of TiO₂. When Au(I) in the solution is along together with Ag(I) and Cu(II) ions, the adsorption of the three ions should be involved. The ion of Cu(II) having smaller size, [29], can be adsorbed faster either than Au (III) and Ag(I). Consequently, the adsorption of Au(III) is inhibited by Cu(II), causing a decrease in the Au(III) adsorption, and so the lower photoreduction.

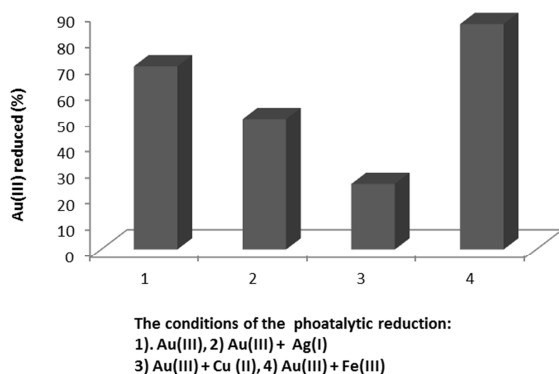

Fig. 6. The influence of other metal ions on the photoreduction.

In the case of Ag(I) interference, based on their size, the adsorption of Ag(I) may be comparable with that of Au(III) ions causing low competition [29]. In addition, the reduction potential of Ag(I) is relatively large, but it is still smaller than that is belonged to Au(III). The low competition in the adsorption and slight smaller reduction potential of Ag(I) explain the lower effect of Ag(I) on decreasing Au(III) photoreduction.

The role of Cu(II) in the depressing Au(III) photoreduction caused by adsorption competition is supported by data obtained from a process without light exposure or in the dark condition as illustrated by Fig.7. It is seen in the figure that adsorption of Au(III) sharply decreased in the presence of Cu(II), but only slightly decreased when Ag(I) is present. The small effect of Ag(I) in Au(III) adsorption may be caused by similar size of both ions.

The interesting phenomena appears regarding the improvement of Au(III) photoreduction in the presence of Fe(III). This ion is also reducible into Fe(II) which is supposed

to be a competition for Au(III) photoreduction, but the opposite data is observed. The reason may be explained as follows. Fe(III) is reduced into Fe(II) ion with the reduction potential as 0.59 V, and Fe(II) is easily oxidized back to form Fe(III) [18]. The oxidation of Fe(II) involves OH radicals formed by H₂O as a media and TiO₂ photocatalyst during UV light exposure. The attachment of OH radicals can prevent the recombination of the OH radical and the electron [24], that keeps the electron in large number. This large number of the electrons should promote the high photoreduction of Au(III).

Fig. 7. The influence of other metal ions on the adsorption.

The influence of Fe(III) on the Au(III) adsorption is also displayed in Fig 7. It is also seen that Fe(III) ion causes a decrease in the Au(III) adsorption, that should also decline the photoreduction. It is clear that the effect of reduction and quick oxidation is stronger than that of the competition on adsorption toward Au(III) photoreduction.

4. Conclusions

It can be concluded that reduction of Au(III) ions in the solution with illuminated TiO₂ photocatalyst has effectively produced gold metal photodeposited on the surface of TiO₂. The yield of the photoreduction is influenced by the illumination time, photocatalyst dose, and initial Au(III) concentrations. The presence of Ag(I) and Cu(II) ions leads to the gold photodeposition decreased due to the competition in adsorption and reduction. In contrast the presence of Fe(III) ion can promote the photoreduction through oxidation-reduction synergic effect.
